MemFaith: Measuring Causal Faithfulness of Memory Agents in Long-Context LLMs

Authors: Dev Sanghvi, Ansh Dabral, Mohamad Kreidieh, Keyuan (Jade) Yan

Date: April 1, 2026

Executive Summary, Success Criteria, and Precise Problem Definition

The advent of ultra-long-context language models and sophisticated memory agents has fundamentally altered the landscape of natural language processing. Recent architectures, such as the MemAgent framework, have demonstrated the capacity to ingest and process arbitrarily long documents—spanning up to 3.5 million tokens—with performance degradation consistently remaining below the five percent threshold.[1] These systems achieve this unprecedented scale by systematically segmenting input streams and maintaining a fixed-length, compressed memory buffer managed via continuous overwrite strategies.[3] However, while the empirical accuracy of these models on retrieval and generation tasks is highly documented, a critical mechanistic question remains unresolved: does the specific contextual information written into and retained by the agent's memory buffer genuinely and causally drive the model's downstream predictions, or is it merely correlative noise that the model ignores in favor of its pre-trained parametric priors?

Initial investigations leveraging the Editability-Faithfulness (EF) metric reveal a stark disconnect between semantic retention and causal utilization. The EF metric, historically evaluated using parametric modification techniques like Rank-One Model Editing (ROME), tests whether perturbing a specific factual association within the model's weights forces a corresponding flip in the model's rationale-based output.[5] When applied to base architectures such as GPT2-XL on the Fact Extraction and VERification (FEVER) benchmark, the EF score hovers at a remarkably low 12.5 percent.[7] This low causal grounding metric indicates that the vast majority of context retained by memory-augmented models does not exert a causal influence on the final generation. Such massive context inefficiency presents a unique opportunity for aggressive, causal-driven context pruning. If the specific chunks of text that actively drive decision-making can be isolated, the surrounding non-causal noise can be aggressively discarded without degrading downstream accuracy.

This document serves as the implementation-first master blueprint for the MemFaith project.

Executed over a highly compressed four-week sprint extending from March 30 to April 20, 2026, this initiative transitions the theoretical framework of Editability-Faithfulness into a highly scalable, inference-time pipeline.[7] Because generating gold-standard EF labels via parametric edits (like ROME) for every textual chunk creates an insurmountable computational bottleneck [7], MemFaith pivots entirely to a Leave-One-Chunk-Out (LOCO) ablation strategy. The primary problem definition requires the system to ingest a long-context query heavily padded with Wikipedia distractors, deterministically segment the context into K discrete chunks, and perform highly parallelized ablation inference.[7] By systematically hiding one chunk at a time from the model and measuring whether the generated answer diverges from the full-context baseline, the system computes the Causal Chunk Score (CCS).

The success criteria for this engineering sprint are strictly defined. First, the team must deliver a fully reproducible, high-throughput CCS computation pipeline capable of running deterministic ablation loops across both single-hop (FEVER) and multi-hop (HotpotQA) datasets.[7] Second, the system must yield empirical degradation curves plotting the CCS against increasing segmentation depths ($K \in \{2, 4, 8, 16\}$) to validate the hypothesis that causal influence dilutes as memory pressure increases.[7] Finally, contingent upon the stability of the core pipeline, the project must demonstrate a behavioral distillation proof-of-concept. This extension requires training a lightweight sequence classifier on the binary causal labels generated during the ablation phase, effectively creating a pre-inference chunk scorer that can prune long contexts dynamically.[7] The ultimate metric of success for this discriminator is its ability to maximize the token reduction ratio while maintaining a 95 percent faithfulness retention rate relative to the full-context baseline answer.

System Architecture Blueprints

To process tens of thousands of LOCO ablations across massive datasets within a constrained temporal and computational budget, the MemFaith system is architected as a strictly decoupled, seven-module data pipeline. This modularity ensures that upstream preprocessing bottlenecks do not stall GPU-bound inference clusters, and that the rigorous mathematical definitions of the causal metrics are preserved without contamination from sampling variance.

The pipeline initiates with the Data Adapter and Long-Context Constructor modules. These components are responsible for transforming pristine, short-form benchmark queries into chaotic, high-pressure memory tasks. The system parses inputs from FEVER and HotpotQA, extracting the gold-standard evidence passages.[7] To simulate the operational environment of an unbounded memory agent, the constructor injects a heavily padded payload of distractor passages sourced from unstructured Wikipedia dumps.[9] The insertion logic randomly interleaves the gold evidence among the distractors to explicitly counteract the "lost in the middle" positional bias frequently observed in contemporary Large Language Models (LLMs).[11]

Module	Input Schema	Output Schema	Architectural Mechanism
Data Adapter	Raw HuggingFace Dataset Object	Normalized JSONL (Query, Gold Label, Evidence)	Standardizes single-hop (FEVER) and multi-hop (HotpotQA) structures.
Long-Context Constructor	Normalized JSONL, Wikipedia Dumps	C_{full} (Token-heavy context), evidence_indices	BM25 retrieval for distractor sampling; randomized concatenation.
Deterministic Chunker	C_{full}, Integer K	List of K String Chunks	spaCy sentence-boundary snapping to prevent semantic fracturing.
Inference Engine	C_{full}, List of C_{-i}	A_{full}, List of A_{-i}	vLLM batched generation; temperature=0.0 for deterministic decoding.
Causal Comparator	A_{full}, List of A_{-i}	Binary Array of Answer Flips (1 or 0)	Regex strict matching (FEVER) or Token-F1/LLM-as-a-judge (HotpotQA).
Evaluation Harness	Binary Arrays, Metadata	Aggregated CCS, Degradation Curves	Computes $CCS(K) = (1/K)$.

Behavioral Distillation	(Query, Chunk, Causal_Label)	Trained Pre-inference Scorer	Binary Cross-Entropy training on a lightweight encoder head.

Following context construction, the text flows into the Deterministic Chunker. A naive character or token-based split would arbitrarily slice through the middle of words or complex semantic structures, resulting in out-of-distribution (OOD) syntactic artifacts that might trigger an answer flip purely due to grammatical destruction rather than genuine causal ablation.[7] To prevent these segmentation artifacts, the module utilizes spaCy (specifically the en_core_web_sm pipeline) for precise sentence boundary detection. The chunker calculates the optimal token length per segment based on the K parameter and snaps the actual division point to the nearest terminal punctuation mark, ensuring that every ablated context C_{-i} remains syntactically coherent.

The High-Throughput Inference Engine represents the computational core of the architecture. Given the multiplicative explosion of inference tasks—where evaluating a single context at $K = 8$ requires nine distinct forward passes (C_{full} plus eight C_{-i} variants)—traditional sequential inference is entirely unfeasible. The system integrates vLLM to maximize GPU utilization via PagedAttention and continuous batching.[7] The engine constructs a micro-batch for each query containing all required context permutations. Crucially, the decoding parameters are permanently locked to greedy decoding (temperature=0.0, top_p=1.0). Any introduction of stochastic sampling variance would fatally compromise the foundational premise of the experiment, as it would become impossible to distinguish an answer flip caused by context ablation from a flip caused by random temperature sampling. Furthermore, an aggressive SQLite or Redis-based caching layer is positioned immediately before the inference engine. If an ablation run crashes or encounters an out-of-memory exception, the caching layer ensures that previously computed A_{full} and A_{-i} responses are instantly retrieved, preserving compute budgets.

Once generation is complete, the Causal Comparator evaluates the divergence between the ablated outputs and the full-context baseline. For the FEVER dataset, which operates within a tightly constrained label space, the comparator utilizes strict regular expressions to map the raw generative text into discrete `` classifications.[7] HotpotQA presents a significantly harder comparison challenge, as the answers are free-form text spans.[7] A naive exact match (EM) would register a false positive causal flip if the model outputs "The Matrix" instead of "Matrix." Therefore, the comparator defaults to Token-level F1 scoring for multi-hop tasks. If the F1 score falls below a predefined threshold (e.g., 0.6), the comparator routes the two answers to a

frozen LLM-as-a-judge module (utilizing an efficient API like GPT-4o-mini) to conclusively determine if the semantic meaning has fundamentally diverged.

Finally, the Evaluation Harness aggregates these binary flip signals to compute the Causal Chunk Score across varying segmentation depths, feeding directly into the optional Behavioral Distillation module. This extension track treats the ablation pipeline as an automated label factory, pairing [Query][Chunk] inputs with the binary causal labels to train a highly efficient, parameter-sparse discriminator capable of executing context pruning in live production environments.

Model / Method Roster and Current Buildable Landscape

The landscape of long-context modeling, memory augmentation, and context pruning has evolved rapidly between 2024 and 2026. Evaluating the causal faithfulness of these systems requires carefully navigating this ecosystem to select architectures that provide reliable, reproducible baselines while acknowledging modern advancements in sequence processing.

Domain Category	Specific Model / Method	Relevance to Implementation Blueprint	Execution Strategy & Viability
Agentic Memory	**MemAgent** (Yu et al., 2025)	Demonstrates the theoretical upper bound of sliding-window memory buffers processing up to 3.5M tokens.[1]	Serves as the primary theoretical motivation.[7] We do not implement their exact RL algorithm, but we test their underlying assumption of memory utilization.
Parametric Editing	**ROME** (Meng et al., 2022)	Represents the legacy "Version A" Editability-Faithfulness metric.[6] Modifies mid-layer MLP weights to test causal belief.[5]	Explicitly deprecated for the main LOCO loop due to massive scaling costs.[7] Acknowledged strictly as historical context.

Primary Baseline	**GPT2-XL** (1.5B)	The mandatory architectural anchor. Required to ensure strict empirical continuity with previous ROME/EF research.[7]	Deployed via HuggingFace transformers for the initial smoke tests. Lightweight enough to run large K ablations on modest hardware.
Modern Baseline	**Qwen2.5-1.5B**	Represents contemporary instruction-tuned models with native long-context support (up to 32k tokens).[13]	Deployed via vLLM as a secondary baseline.[7] Used to verify if causal dilution is a universal LLM trait or a relic of older architectures.
Context Pruning	**LLMLingua / LLMLingua-2**	State-of-the-art token-level and phrase-level pruning frameworks that leverage perplexity and surprisal.[15]	Serves as the primary ideological competitor.[17] We hypothesize that our causally-trained discriminator will outperform perplexity-based methods.
Evaluation Frameworks	**HELMET / RULER**	Provide standardized methodologies for extending short QA tasks into 128k+ long-context needles-in-haystacks.[9]	We adapt their specific distractor injection recipes to scale FEVER and HotpotQA into valid memory-pressure benchmarks.[9]

The decision to maintain GPT2-XL (1.5B parameters) as the primary baseline is mathematically and historically necessary.[7] The foundational metric we are evolving—Editability-Faithfulness—was deeply calibrated on GPT2-XL using Rank-One Model Editing.[6] If the project were to immediately abandon this architecture in favor of a massive contemporary model like Llama-3 70B, it would be impossible to determine whether changes in

causal faithfulness were due to the shift from parametric editing to LOCO ablation, or simply artifacts of a highly advanced attention mechanism. However, to ensure the findings remain relevant to the current buildable landscape, Qwen2.5-1.5B is integrated as a shadow baseline.[7] Qwen2.5-1.5B natively supports massive context windows and advanced instruction tuning, providing a rigorous modern counterpoint to the older GPT2-XL architecture.[13]

For the behavioral distillation extension, the competitive landscape is currently dominated by perplexity-based pruning methods like LLMLingua and Selective Context.[15] These systems evaluate the "surprisal" of tokens and prune those that the model finds highly predictable.[16] However, perplexity is a measure of syntactic predictability, not causal necessity. A token might be highly predictable yet absolutely critical to the logical reasoning chain. MemFaith's trained chunk scorer bypasses surprisal entirely, training directly on the empirical causal labels generated by the LOCO ablation loop, providing a fundamentally different and theoretically superior approach to context reduction.

Dataset Options and Preprocessing Strategy

The experimental integrity of the Causal Chunk Score relies entirely on the quality of the long-context construction. Feeding a model a context comprised of random, disjointed noise fails to replicate the operational pressures of a true memory agent. The data preprocessing strategy must intelligently fuse high-signal gold evidence with distributionally similar distractor passages to create an environment where identifying the causal chunk is genuinely difficult.

FEVER (Fact Extraction and VERification) serves as the primary single-hop analysis vehicle.[7] FEVER provides a meticulously annotated set of claims mapped to specific Wikipedia evidence sentences, coupled with a constrained, clean label space (SUPPORTS, REFUTES, NOT ENOUGH INFO).[7] This clean label space is mathematically crucial for the early stages of the pipeline, as it allows the Causal Comparator to execute flawless, programmatic string matching without the noise introduced by semantic ambiguity.[7]

HotpotQA provides the necessary complexity for testing Hypothesis 2, which posits that multi-hop tasks will exhibit more distributed and fragile causal structures.[7] HotpotQA questions are designed so that the model must synthesize information from at least two distinct Wikipedia documents.[18] In the context of LOCO ablation, if the model requires both Chunk A and Chunk B to reason effectively, removing either chunk should independently trigger an answer flip.

To transform these datasets into long-context evaluations, we adopt the distractor injection methodologies established by the HELMET and RULER benchmarks.[9] The preprocessing strategy executes the following sequence:

1. **Gold Evidence Extraction:** Isolate the exact sentences or paragraphs explicitly annotated as necessary for resolving the query.[18]
2. **Distractor Retrieval:** Utilizing BM25 or dense retrieval (e.g., Contriever), search a unified

Wikipedia dump to extract M passages that are semantically similar to the query but lack the causal facts required to answer it. The use of distributionally similar distractors, rather than random text, prevents the LLM from relying on simple semantic clustering to find the answer.[20]

3. **Context Assembly:** Concatenate the gold evidence and the M distractors. The position of the gold evidence must be randomized uniformly across the sequence. If the evidence is consistently placed at the beginning or end of the prompt, the LLM's inherent "lost in the middle" bias will skew the CCS metric, as chunks near the boundaries will register artificially high causal influence simply due to their position.[11]
4. **Format Standardization:** Wrap the final assembled context in a rigid prompt template: You are a highly accurate fact-verification assistant. Read the following context carefully. [Context] {long_context} [Query] {claim/question}.

Training Pipeline and Experiment Plan

Because the core of MemFaith relies on inference-time ablation, the traditional concept of an epoch-based training pipeline is localized entirely within the Extension Track (Behavioral Distillation). The experiment plan is defined by a massive, programmatic generation loop followed by a focused, lightweight training phase.

The experimental execution begins with the **Causal Label Generation Loop**. The pipeline ingests the preprocessed FEVER and HotpotQA contexts. For a given context C, the Deterministic Chunker slices the text into $K \in \{2, 4, 8, 16\}$ segments.[7] The Inference Engine first executes the forward pass on C_{full} to establish the baseline A_{full}. Immediately following, the engine executes K parallel forward passes, sequentially masking each C_i. The Causal Comparator ingests the outputs and generates a binary vector of length K. If $A_{-i} \neq A_{full}$, the label for chunk i is 1 (Causally Necessary). If $A_{-i} == A_{full}$, the label is 0 (Causally Irrelevant). This process is repeated across 10,000 queries, resulting in a dense dataset mapping exact text chunks to empirical causal utility.

Once the causal dataset is generated, the pipeline transitions to the **Behavioral Distillation** phase.[7] The objective is to train a sequence classifier that mimics the teacher model's sensitivity to causal interventions without requiring the massively expensive LOCO loop at runtime.

- **Architecture:** We utilize the base weights of Qwen2.5-0.5B topped with a simple linear classification head. This ensures the scorer is computationally negligible compared to the massive generation models.
- **Input Formatting:** The inputs are formatted as [Query]. The scorer must learn to evaluate

the causal utility of the chunk strictly relative to the active query.

- **Loss Formulation:** Given the hypothesis that causal chunks are highly sparse (H3), the resulting dataset will suffer from extreme class imbalance (a vast majority of 0 labels).[7] Training with standard Cross-Entropy will cause the model to collapse into predicting 0 universally. We mitigate this by training with **Focal Loss**, aggressively down-weighting the loss contribution of easily classified distractors and forcing the gradients to focus on the rare, causally vital chunks.
- **Optimization:** The model is trained using AdamW with a learning rate of 2e-5, a weight decay of 0.01, and a linear warmup over the first 10 percent of steps, executing for a maximum of 3 epochs to prevent overfitting on the synthetic LOCO labels.

Evaluation Framework and Metrics

The evaluation framework is engineered to prove that the Causal Chunk Score accurately reflects the underlying mechanics of memory agents, moving beyond theoretical assumptions to empirical proof.

The foundational metric is the **Causal Chunk Score (CCS)**. For a given context segmented into K chunks, it is computed as:

$$CCS(K) = \frac{1}{K} \sum_{i=1}^{K} \mathbf{1}(A_{-i} \neq A_{full})$$

This yields a percentage representing the average answer-flip rate.[7] A high CCS implies a fragile, highly interdependent causal structure where almost every chunk matters. A low CCS implies extreme sparsity, where the vast majority of the context can be ablated without impacting the model's reasoning.[7]

To evaluate Hypothesis 1 (Dilution), the primary visual output of the project is the **CCS Degradation Curve**.[7] The framework plots CCS on the y-axis against increasing values of K on the x-axis. If the hypothesis holds, the curve will exhibit a distinct downward trajectory. As memory pressure increases and chunk granularity becomes finer, the causal weight of any individual chunk is hypothesized to dilute, exposing the inefficiency of the memory agent's overwrite strategy.[7]

The evaluation suite relies heavily on **Stratified Analysis** to uncover hidden behavioral biases.[7]

- **Label-Based Stratification:** On the FEVER dataset, the harness slices the CCS metrics by the gold label (SUPPORTS vs REFUTES). This isolates whether LLMs require more rigorous causal evidence to refute a false claim compared to supporting a true one.
- **Positional Stratification:** To control for the "lost in the middle" effect, the harness maps the causal labels back to their absolute position in the prompt (e.g., first 20%, middle

60%, last 20%). This allows the team to quantitatively prove whether chunks placed in the middle of a context are systematically ignored by the model's attention mechanisms, regardless of their actual information content.

For the Discriminator Extension, the evaluation shifts to operational efficiency metrics. The trained chunk scorer is placed in front of the inference engine as a pre-processor. The evaluation harness computes the **Token Reduction Ratio** (percentage of context safely discarded) plotted against **Accuracy Retention** (percentage of A_{pruned} outputs that perfectly match A_{full}). This generates a classic Pareto frontier, allowing systems engineers to select a pruning threshold τ that maximizes latency reduction while maintaining an acceptable causal accuracy bound.[7]

Runtime / Deployment / Export Plan

To process the massive volume of parallel ablations, the runtime architecture is fundamentally decoupled. The bottleneck in LOCO analysis is the KV-cache recomputation for identical prefixes.

Inference Serving: The architecture mandates the deployment of vLLM to handle all forward passes.[7] By utilizing PagedAttention and continuous batching, vLLM significantly reduces the memory overhead of processing K simultaneous variations of a 30k-token prompt. The inference engine submits the A_{full} request alongside all C_{-i} variants simultaneously, allowing the CUDA kernels to maximize throughput.

Caching Layer: An absolute operational requirement is a robust intermediate caching layer.[7] Due to the probabilistic nature of API timeouts and out-of-memory (OOM) errors during heavy context loads, the pipeline must not lose progress. The architecture implements an SQLite or Redis-backed cache utilizing a composite hash key: hash(model_version + prompt_text + generation_params). Before submitting a request to vLLM, the inference engine checks the cache. If an ablation run fails at chunk $i = 7$, the system can immediately resume and retrieve chunks 1 through 6 from disk, saving massive amounts of compute time and budget.

Discriminator Export: Upon successful training of the behavioral distillation module, the lightweight chunk scorer will be packaged and exported using ONNX Runtime. Exporting the Qwen2.5-0.5B head to ONNX ensures that the causal pruner can be deployed on CPU or low-end edge devices. This enables a deployment architecture where a local edge device quickly scores and prunes a massive document, transmitting only the highly causal, compressed chunks over the network to the heavy cloud-based GPT2-XL/Qwen2.5-1.5B API for final reasoning.

Failure Modes and Mitigation Strategies

The transition from a theoretical metric to an automated, high-throughput pipeline introduces several critical failure modes that must be aggressively mitigated.

Failure Mode	Operational Symptom	Engineering Mitigation Strategy
Sloppy Answer Comparison	HotpotQA Exact Match fails due to minor formatting (e.g., "The Matrix" vs "Matrix"), artificially inflating the CCS by logging false-positive answer flips.[7]	Implement Token-level F1 scoring for multi-hop tasks. Integrate a strict LLM-as-a-judge fallback (e.g., GPT-4o-mini) triggered only when F1 falls into ambiguous thresholds ($0.4 < \mathrm{F1} <$).[7]
Segmentation Artifacts	CCS becomes highly volatile. Chunks cut mid-word or mid-sentence generate out-of-distribution syntactic noise, causing the LLM to flip its answer due to grammar failure rather than causal ablation.[7]	Abandon strict token-count splits. Mandate the use of spaCy sentence-boundary detection. The chunker must calculate the optimal split and "snap" the boundary to the nearest terminal punctuation mark.
Compute Explosion	Processing $K =$ across 10,000 queries exceeds the 4-week compute budget, leading to abandoned runs.[7]	Enforce aggressive SQLite caching. If timelines slip, implement representative sub-sampling, executing high-K runs on a statistically significant 1,000-example slice rather than the full dataset.[7]
Model Incompetence	GPT2-XL fails to follow instructions in the heavily padded distractor context, resulting in a baseline	Establish an accuracy floor (e.g., 50% on FEVER). If GPT2-XL cannot meet this, instantly trigger the

	A_{full} accuracy near random chance.[7]	contingency to promote the modern **Qwen2.5-1.5B** to the primary mainline model.[7]
Structural Ambiguity	The narrative of the project becomes blurry, confusing audience members about whether the goal is ROME parametric editing or chunk ablation.[7]	Enforce strict hierarchical framing: Memory Agents are the motivation, Chunk Ablation is the core semester method, and the Discriminator is strictly an optional extension.[7]

Reproducibility Checklist

To ensure the project yields scientifically valid and reproducible results across different hardware setups, the following criteria must be met prior to project freeze on April 20:

- [ ] **Dependency Lock:** A strict conda environment.yml or uv.lock file containing exact hashes for vLLM, transformers, spaCy, and torch.
- [ ] **Deterministic Sampling:** All distractor sampling and Wikipedia injection functions utilize a fixed pseudo-random number generator (PRNG) seed. Running the Long-Context Constructor twice must yield byte-for-byte identical context strings.
- [ ] **Generation Determinism:** The temperature parameter is strictly locked to 0.0, with top_p=1.0 and do_sample=False enforced in the inference engine wrappers to guarantee that A_{full} and A_{-i} are not subject to sampling variance.
- [ ] **Cache Hygiene:** The SQLite/JSONL cache databases are versioned and stored via Git LFS or HuggingFace Datasets, allowing third-party reviewers to audit the exact raw outputs before comparator evaluation.
- [ ] **One-Command Execution:** The evaluation harness is packaged into a single shell script (run_eval.sh) that ingests the raw cache files and deterministically outputs the final CCS tables and degradation curve plots without manual intervention.

Week-by-Week Execution Plan

The execution is bound to an aggressive, decision-driven four-week schedule.

- **Week 1 (Mar 30 - Apr 5): Scope Lock and Core Pipeline Build**
  - **Focus:** Infrastructure scaffolding. Finalize the scope, ensuring the CCS pipeline is the core priority. Build the FEVER and HotpotQA long-context builders and the deterministic spaCy chunking utilities.[7]
  - **Deliverables:** A finalized SQLite result schema and an end-to-end smoke test proving the integration of the Data Adapter through to the Inference Engine on a

small 100-sample subset.[7]
    - **Decisions:** Lock the exact K values (defaulting to $\{2, 4, 8, 16\}$) and formally decide if GPT2-XL passes the accuracy floor or if Qwen2.5-1.5B must be promoted.[7]
- **Week 2 (Apr 6 - Apr 12): Main Ablation Runs on FEVER**
    - **Focus:** Execution at scale. Deploy the LOCO ablation runner against the vLLM endpoints.[7]
    - **Deliverables:** Complete all FEVER experiments across all locked K values. Develop the CCS computation scripts to parse the outputs and generate the initial degradation curves and failure-case analyses.[7]
- **Week 3 (Apr 13 - Apr 19): Secondary Dataset and Deeper Analysis**
    - **Focus:** Multi-hop complexity and hypothesis testing. Stabilize the HotpotQA adaptation, implementing the F1/LLM-as-a-judge comparator.[7]
    - **Deliverables:** HotpotQA CCS runs across all K values. Stratified analysis comparing single-hop vs multi-hop causal dilution, and positional bias evaluation.[7]
    - **Trigger:** If the core pipeline is completely stable by mid-week, officially authorize the Extension Track to begin training the chunk scorer.[7]
- **Week 4 (Apr 20 - Apr 26): Extension, Polish, and Final Delivery**
    - **Focus:** Packaging and synthesis. Absolutely no new research directions are permitted.[7]
    - **Deliverables:** Finalized tables, plots, and meticulously formatted case studies. Execution of the reproducibility scripts. Completion of the final proposal-report text and presentation slides.[7]
    - **Extension (if triggered):** Deliver the prototype chunk scorer and the Token Reduction vs. Accuracy Retention Pareto curves.[7]

Prioritized Action Items

1. **Develop the Causal Comparator Logic (High Priority):** Before scaling inference, the exact string-matching regex for FEVER and the F1/LLM-judge logic for HotpotQA must be unit-tested against synthetic edge cases. Sloppy comparator logic is the primary risk to metric integrity.[7]
2. **Establish the vLLM + SQLite Caching Pipeline (High Priority):** The massive $O(K \times N)$ multiplier of LOCO ablation demands immediate integration of vLLM continuous batching backed by a fail-safe SQLite state manager to protect compute budgets.[7]
3. **Build the Deterministic Chunker (Medium Priority):** Implement the spaCy sentence-boundary snapping logic to ensure chunks are cleanly divided, preventing grammatical out-of-distribution artifacts from polluting the causal signals.[7]
4. **Execute the Baseline Accuracy Test (Medium Priority):** Run GPT2-XL on 500

un-ablated long-context FEVER prompts. If accuracy is near random chance, trigger the contingency protocol to utilize Qwen2.5-1.5B.[7]

5. **Provision the Discriminator Training Loop (Low Priority):** Prepare the sequence classification scripts (Binary Cross-Entropy with Focal Loss) in a dormant state, ready to ingest the ablation labels if the Week 3 extension trigger is authorized.

Title: Project Analysis: MemFaith Causal Faithfulness
Date: April 1, 2026

Executive Summary
MemFaith is a highly focused, four-week graduate NLP engineering project designed to measure whether long-context Large Language Models (LLMs) genuinely rely on causal evidence. Moving beyond the semantic approximations of "Retrieval-Augmented Generation" (RAG) paradigms, MemFaith implements **Leave-One-Chunk-Out (LOCO) ablation** to isolate the causal necessity of individual context chunks. The project establishes a novel evaluation metric—the **Causal Chunk Score (CCS)**—and optionally culminates in a behaviorally distilled chunk-scorer capable of aggressively pruning long contexts without causing downstream performance degradation.

Problem Formulation and Scope
* **The Illusion of Memory:** While models such as MemAgent can ingest up to 3.5M tokens, prior parametric editing metrics (like Editability-Faithfulness via ROME) suggest that the vast majority of retained context does not causally drive the final output.[1, 7]
* **Scope Pivot:** Because parametric weight editing is computationally prohibitive at scale, MemFaith pivots entirely to inference-time **chunk ablation**. It tests causal necessity by asking: *If chunk i is removed from the prompt, does the model's answer flip?*
* **Core Metric:** Causal Chunk Score is defined mathematically as $CCS(K) = (1/K) \sum_{i} Pr[A_{-i} \neq A_{full}]$.

Architecture Deep-Dive
To ensure rigorous causal measurement, the system architecture operates across a strict 7-stage pipeline :
1. **Data Adapter:** Normalizes the query and evidence schemas for FEVER (single-hop) and HotpotQA (multi-hop).
2. **Long-Context Constructor:** Injects distributionally similar Wikipedia distractors around the gold evidence to simulate memory pressure.
3. **Deterministic Chunker:** Splits the context into K chunks, utilizing `spaCy` sentence-boundary detection to prevent arbitrary semantic fracturing mid-word.
4. **Inference Engine:** A batched, highly cached generation loop (enforcing

`temperature=0.0`) that evaluates the full context alongside all K ablated permutations.
5. **Causal Comparator:** Evaluates answer flips. Uses strict regex string matching for FEVER, and Token-F1 coupled with an LLM-as-a-judge fallback for the free-form text of HotpotQA.
6. **Evaluation Harness:** Aggregates CCS scores and plots degradation against increasing values of K.
7. **Behavioral Distillation (Extension):** Trains a lightweight classifier head on the binary causal labels to serve as an efficient pre-inference pruner.

Model/Method Landscape
* **Primary Baseline:** GPT2-XL (1.5B) serves as the architectural anchor, maintaining strict empirical continuity with historical ROME/EF benchmarks.
* **Modern Competitor:** Qwen2.5-1.5B acts as a secondary baseline, ensuring the findings hold up against modern, instruction-tuned models with massive native context windows.
* **Pruning Baselines:** Frameworks like LLMLingua and Selective Context serve as ideological competitors to the causal-scorer extension, relying on syntactic surprisal rather than empirical causal necessity.

Dataset and Preprocessing Analysis
* **FEVER:** Selected for its rigidly controlled `` label space, allowing for flawless programmatic measurement of causal flips.
* **HotpotQA:** Essential for testing multi-hop reasoning, assessing whether causal dependency is distributed across multiple chunks.
* **Distractors:** Sourced via BM25 retrieval from Wikipedia dumps and interleaved randomly to counteract the LLM "lost in the middle" positional bias.

Evaluation Framework
* **CCS Degradation Curve:** The primary analytical output, testing the hypothesis (H1) that finer segmentation dilutes causal influence across the prompt.
* **Stratification:** The harness slices CCS data by label type (e.g., analyzing if `REFUTES` claims require higher causal dependency) and absolute chunk position.
* **Pruning Efficiency:** The discriminator extension is evaluated by plotting the Token Reduction Ratio against Full-Context Accuracy Retention.

Training/Deployment Strategy
The core CCS pipeline requires no training, relying entirely on inference-time ablation. The training strategy is isolated to the **Extension Track**.
* **Behavioral Distillation:** Treating the ablation loop as a label-generator, the pipeline pairs `[Query][Chunk]` inputs with binary causal labels to train a fast sequence classifier (e.g., a Qwen2.5-0.5B head) using Focal Loss to account for extreme class imbalance.
* **Deployment:** The resulting scorer acts as an ONNX-exported pre-processing filter, discarding low-value tokens at the edge before they hit the expensive LLM context window.

Schedule

The project is constrained to a highly aggressive 4-week sprint (Mar 30 - Apr 20, 2026) :
* **Week 1:** Pipeline scaffolding, long-context construction, and end-to-end smoke testing.
* **Week 2:** FEVER ablation runs at scale; generation of initial CCS tables and curves.
* **Week 3:** HotpotQA adaptation; triggering the Distillation Extension if the core pipeline is stable.
* **Week 4:** Metric aggregation, final plotting, report writing, and reproducibility packaging.

Risks and Failure Modes
* **Metric Integrity Loss:** Sloppy answer matching on HotpotQA generates false "flips," destroying CCS validity. *Mitigation: Strict F1 scoring combined with an LLM-as-a-judge fallback.*.
* **Segmentation Artifacts:** Arbitrary token splitting cuts mid-sentence, causing flips due to grammatical destruction rather than causal necessity. *Mitigation: Strict sentence-boundary snapping.*.
* **Compute Explosion:** Running $K=16$ across tens of thousands of queries is computationally prohibitive. *Mitigation: Aggressive SQLite caching and representative sub-sampling for high K runs.*.

Strengths
* **Actionability:** Significantly more scalable and buildable than full parametric weight editing (ROME).
* **Empirical Rigor:** Provides clear, empirical evidence of causal necessity over mere semantic similarity, differentiating it sharply from basic RAG implementations.
* **Clear Metric:** The CCS provides a highly readable, quantifiable metric for tracking memory efficiency.

Potential Gaps / Concerns
* **Weaker Intervention:** Inference-time ablation is theoretically "weaker" than surgical weight editing, requiring careful narrative framing to satisfy academic rigor.
* **Synergistic Relevance:** Single-chunk ablation completely ignores synergistic relevance—scenarios where chunks A and B are useless individually but critically causal when combined.
* **Scope Creep:** Over-focusing on the Discriminator extension before the CCS baseline is fully proven threatens overall project completion.

work_division.md

Title: Team Execution Plan: MemFaith
Date: April 1, 2026
Team: Dev Sanghvi, Ansh Dabral, Mohamad Kreidieh, Jade Yan

1. Ownership Domains

The MemFaith project pipeline is strictly divided into four functional domains to ensure the aggressive 4-week schedule is met without overlapping bottlenecks. The structure ensures the core Causal Chunk Score (CCS) pipeline is prioritized, protecting against scope drift.

Dev Sanghvi — Technical Lead: Core ML & CCS Logic

* **Domain:** Overall technical direction, design of the Leave-One-Chunk-Out (LOCO) ablation logic, answer comparison functions, and final metric (CCS) formulation. Owns the mathematical correctness of the causal intervention.
* **Week-by-Week Deliverables:**
  * *Week 1 (Mar 30):* Finalize exact mathematical definitions of CCS. Design the inference loop logic to support K segmentations. Establish the GPT2-XL baseline wrappers.
  * *Week 2 (Apr 6):* Implement exact-match and semantic flip-detection logic for FEVER. Execute the first wave of hypothesis testing (H1: Dilution).
  * *Week 3 (Apr 13):* Design Token-F1 and LLM-as-a-judge comparison logic for HotpotQA. Evaluate H2 (Multi-hop distributed structures).
  * *Week 4 (Apr 20):* Lead final metric analysis, finalize degradation curves, and frame the final conclusions for the report.
* **Key Files / Components Owned:** `inference_engine.py`, `causal_comparator.py`, `ccs_metrics.py`.

Ansh Dabral — Implementation: Infra, Scale & Caching

* **Domain:** Orchestration of the high-throughput pipeline, `vLLM` integration, caching architectures, runtime hygiene, and reproducibility.
* **Week-by-Week Deliverables:**
  * *Week 1 (Mar 30):* Set up `vLLM` inference endpoints for batched generation. Build the SQLite/JSONL caching layer to prevent recomputing A_{full}.
  * *Week 2 (Apr 6):* Execute the massive FEVER ablation runs at scale across $K \in \{2, 4, 8, 16\}$. Manage GPU memory limits and batching thresholds.
  * *Week 3 (Apr 13):* Scale the HotpotQA runs. Ensure fault-tolerant resumes if instances crash during long runs.
  * *Week 4 (Apr 20):* Finalize reproducibility scripts, Docker containers, and locked `requirements.txt` environment files.
* **Key Files / Components Owned:** `batch_runner.py`, `cache_manager.py`, `environment.yml`, `run_all.sh`.

Mohamad Kreidieh — Extension Track: Behavioral Distillation

* **Domain:** The optional but high-value chunk-scorer discriminator, chunk-level label generation utilities, pruning experiments, and token-reduction metrics.
* **Week-by-Week Deliverables:**
  * *Week 1 (Mar 30):* Shadow core pipeline setup; prepare binary sequence classification training loops using HuggingFace `Trainer`.
  * *Week 2 (Apr 6):* Ingest early FEVER ablation results, transforming the flip flags into `(Query, Chunk, Label)` training pairs.

  * *Week 3 (Apr 13):* Train the lightweight discriminator (e.g., Qwen2.5-0.5B head) on the causal labels using Focal Loss.
  * *Week 4 (Apr 20):* Execute pruning-vs-performance evaluations. Generate latency and token reduction tradeoff Pareto curves.
* **Key Files / Components Owned:** `train_discriminator.py`, `pruning_evaluator.py`, `scorer_model.py`.

Jade Yan — Data, Protocols & Documentation
* **Domain:** Dataset curation (FEVER/HotpotQA), long-context distractor injection, deterministic chunking protocols, and final report structuring.
* **Week-by-Week Deliverables:**
  * *Week 1 (Mar 30):* Build the Long-Context Constructor. Inject Wikipedia distractors via BM25 for FEVER and HotpotQA. Implement `spaCy`-based deterministic chunking.
  * *Week 2 (Apr 6):* Verify dataset normalization and ensure chunk borders do not shatter semantic meaning.
  * *Week 3 (Apr 13):* Generate evaluation tables, format case studies (e.g., extracting qualitative examples of "causal distractors").
  * *Week 4 (Apr 20):* Write up the final survey structure, format the methodology sections, and polish presentation slides.
* **Key Files / Components Owned:** `data_adapter.py`, `context_constructor.py`, `chunker.py`, `final_report.tex`.

---

2. Shared Responsibilities
* **Paper Writing:** All members draft methodology and results sections related to their specific domains. Jade owns final formatting and narrative flow.
* **Code Reviews:** All Pull Requests to the `main` branch require at least one approving review from a cross-domain owner to ensure integration sanity.
* **Bug Triage:** Handled collectively during Wednesday check-ins.

---

3. RACI-Style Ownership Matrix

Component	Dev (Core Logic)	Ansh (Infra)	Mohamad (Extension)	Jade (Data/Docs)
Dataset & Context Builders	C	I	I	**R/A**
Chunking Logic	C	I	I	**R/A**
Inference Engine & Caching	C	**R/A**	I	I
Causal Comparator (Flips)	**R/A**	I	C	I
CCS Metric Aggregation	**R/A**	C	I	C
Discriminator Training	I	C	**R/A**	I

| **Final Report & Formatting** | A | C | C | **R/A** |

(R=Responsible, A=Accountable, C=Consulted, I=Informed)

---

4. Weekly Sync Structure
* **Monday (45 min): Sprint Planning.** Review the week's goals. Lock parameters (e.g., exact K values, model deployment limits).
* **Wednesday (20 min): Blocker Triage.** Standup format. Address compute bottlenecks, `vLLM` crashes, or data parsing errors.
* **Friday (60 min): Integration & Metric Review.** Run the end-to-end pipeline on a subset of data. Review current CCS degradation graphs to verify mathematical soundness.

---

5. Critical Integration / Handoff Points
* **Handoff 1 (Week 1):** Jade hands off the finalized, deterministic long-context strings and chunk mappings to Ansh for inference testing.
* **Handoff 2 (Week 2):** Ansh hands off the cached inference outputs (A_{full}, A_{-i}) to Dev for the Causal Comparator evaluation.
* **Handoff 3 (Week 3):** Dev exports the verified `.csv` of causal labels to Mohamad to trigger the Distillation training phase.

---

6. Decision Checkpoints
* **Week 1 (Mar 30):** Lock exact K values. *Default: {2, 4, 8, 16}.*
* **Week 2 (Apr 6):** Decision to promote Qwen2.5-1.5B over GPT2-XL if the GPT2 baseline fails to follow basic prompt instructions in the presence of heavy distractors.
* **Week 3 (Apr 13):** Trigger decision for Mohamad's Extension Track. *Condition: The core FEVER ablation pipeline must be 100% stable before training begins.*.

dev_work_division.md

Title: Master Implementation Plan — Dev Sanghvi
Role: Technical Lead (Core ML, CCS Logic, & Evaluation)
Date: April 1, 2026

1. Role and Scope
As the Technical Lead, I own the mathematical and programmatic definition of the Causal Chunk Score (CCS). My responsibility is ensuring that the interventions (Leave-One-Chunk-Out ablation) are scientifically valid, that answer comparisons are strictly rigorous to prevent metric

decay, and that the final hypothesis testing (Dilution and Multi-hop patterns) is executed without methodological flaws.

2. Phase Breakdown and Weekly Deliverables

Phase 1: Logic & Comparator Scaffolding (Week 1: Mar 30 - Apr 5)
Goal: Define the exact comparison hooks and logic boundaries for the ablation loop.
* **Concrete Subcomponents:**
  * **Exact-Match Logic:** Implement `CausalComparator` for FEVER. Given $A_{full} \in \{\text{SUPPORTS, REFUTES, NEI}\}$, write strict regex parsing to extract the model's intent from greedy decoded text.
  * **HotpotQA Evaluator Stub:** Implement Token-F1 scoring. Write a prompt wrapper for a frozen LLM-as-a-judge (e.g., `gpt-4o-mini` API) to evaluate if A_{-i} semantically diverges from A_{full}.
  * **CCS Aggregator:** Implement the `ccs_metrics.py` module to calculate $CCS(K) = (1/K) \sum \mathbf{1}(A_{-i} \neq A_{full})$.
* **Validation Performed / Acceptance Checks:** Create 50 unit tests with hardcoded, synthetic model outputs to guarantee the `CausalComparator` never registers a false positive flip due to formatting artifacts.

Phase 2: FEVER Pipeline Integration (Week 2: Apr 6 - Apr 12)
Goal: Connect the comparator to Ansh's inference runner and analyze the first massive data pull.
* **Concrete Subcomponents:**
  * **Data Integration:** Hook the comparator to the SQLite/JSONL cache generated by the batched `vLLM` runner.
  * **Stratification Logic:** Write Pandas/NumPy logic to slice CCS scores by FEVER label to calculate if `REFUTES` claims have a higher causal dependency than `SUPPORTS`.
  * **Context-Position Analysis:** Map $chunk_i$ to its relative position in the prompt. Plot causal importance against position to analyze "lost in the middle" effects.
* **Validation Performed / Acceptance Checks:** Verify that $K=0$ (baseline full context) maintains at least 65% accuracy on the FEVER ground-truth labels before trusting the ablation flips. If the model is guessing randomly, the flips are meaningless.

Phase 3: Multi-Hop Adaptation & Handoff (Week 3: Apr 13 - Apr 19)
Goal: Prove Hypothesis 2 (Multi-hop tasks exhibit distributed causal patterns).
* **Concrete Subcomponents:**
  * **HotpotQA Flip Measurement:** Execute the Token-F1 and LLM-judge logic on HotpotQA ablation runs.
  * **Multi-Chunk Dependency Analysis:** Analyze if removing Chunk A causes an answer flip, but removing Chunk B *also* causes a flip, mathematically proving distributed causal necessity.
  * **Discriminator Handoff:** Export a clean, verified `.csv` of `(query, chunk_text, causal_label)` to Mohamad to trigger the Extension Track training.

* **Validation Performed / Acceptance Checks:** Manual qualitative review of 100 HotpotQA flips to ensure the LLM-as-a-judge isn't hallucinating semantic divergence where none exists.

Phase 4: Synthesis & Hypothesis Testing (Week 4: Apr 20 - Apr 26)
Goal: Finalize the narrative, generate final plots, and conclude the research.
* **Concrete Subcomponents:**
  * **Degradation Curves:** Use `matplotlib/seaborn` to generate final publication-ready plots of CCS vs K.
  * **Case Study Extraction:** Work with Jade to pull 6 distinct qualitative examples (e.g., a distractor that caused a flip, a gold evidence that did *not* cause a flip).
  * **Final Methodology Writeup:** Author the "Methodology" and "Results" sections of the final LaTeX report.
* **Validation Performed / Acceptance Checks:** Ensure the degradation curves accurately scale with K and that all qualitative case studies perfectly align with the mathematical output of the `CausalComparator`.

3. Key Magic Numbers / Hyperparameters / Decision Knobs to Tune
As the logic owner, I strictly enforce the following hyperparameters across the codebase to protect metric integrity:
* **Decoding Temperature:** `0.0` (Must be deterministic. Stochastic sampling variance ruins causal ablation and generates false flips).
* **Top_P:** `1.0` (Disabled to ensure strict greedy decoding).
* **Max Context Budget:** `16,384` tokens (Ensures the prompts fit comfortably in 80GB VRAM while applying significant memory pressure via distractors).
* **K (Segmentation Depths):** $\{2, 4, 8, 16\}$.
* **LLM Judge Threshold:** Token-F1 < 0.6 triggers the LLM-as-a-judge secondary verification for HotpotQA.

4. Final Summary Checklist
* [ ] `CausalComparator` regex and F1 logic fully unit tested.
* [ ] $K=0$ baseline accuracy verified >65%.
* [ ] CCS degradation curves plotted for FEVER.
* [ ] Multi-hop distributed causal logic mapped for HotpotQA.
* [ ] Causal labels `.csv` successfully handed off to Mohamad.
* [ ] Qualitative case studies extracted and verified.
* [ ] Methodology section written and pushed to main repo.

walkthrough.md

Title: Walkthrough: MemFaith Reverse-Engineering & Artifact Generation
Date: April 1, 2026

1. What Was Done

This package reverse-engineers the structural, organizational, and tonal rigor of the reference project ("Uncertainty-Calibrated Collision-Risk Forecasting") and applies it to the target user project: **"MemFaith: Measuring Causal Faithfulness of Memory Agents in Long-Context LLMs."**

The raw inputs for MemFaith consisted of a research proposal, a master blueprint, a project analysis memo, and a research plan. These inputs outlined an ambitious goal to use chunk-ablation to measure the causal grounding of LLMs over a highly compressed 4-week academic sprint. This task transformed those conceptual outlines into a concrete, highly actionable execution package suitable for an engineering team.

2. Artifacts Created and What Each Covers

* **`deep-research-report.md`:** The master architectural blueprint. It defines the strict 7-module pipeline (Data $\rightarrow$ Constructor $\rightarrow$ Chunker $\rightarrow$ Inference $\rightarrow$ Comparator $\rightarrow$ Harness $\rightarrow$ Discriminator). It establishes the exact metrics (CCS), defines the deployment stack (`vLLM`, `spaCy`), explicitly outlines how the distractor-injection and ablation inference loops function, and evaluates the model landscape (GPT2-XL vs Qwen2.5, LLMLingua vs Behavioral Distillation).
* **`paper_analysis.md`:** A structured, readable summary for high-level understanding. It isolates the project's pivot from parametric weight editing (Version A / ROME) to inference-time chunk ablation (Version B / CCS). It maps out the strengths, gaps, and strict phase-gating required to prevent scope creep.
* **`work_division.md`:** The complete team execution plan for the 4-person team (Dev, Ansh, Mohamad, Jade). It maps the 4-week timeline to specific deliverables, sets up a RACI matrix, establishes file ownership, and mandates a rigid Mon/Wed/Fri synchronization cadence.
* **`dev_work_division.md`:** The personal implementation plan for Dev Sanghvi (Technical Lead). It breaks down his specific tasks by week, focusing heavily on the mathematical logic of the CCS metric, the exact-match vs semantic-match comparison hooks, and the specific hyperparameters ("magic numbers") he must enforce (e.g., `temperature=0.0`).

3. Key Findings and Structural Decisions
* **Necessity of Caching:** The 4-week timeline is incredibly aggressive for running large-scale Leave-One-Chunk-Out (LOCO) ablations. To compensate, the infrastructure plan explicitly mandates an SQLite/JSONL caching layer (owned by Ansh) to prevent recomputing the full-context baselines.
* **Comparator Brittleness:** The target inputs noted the risk of "sloppy answer comparison" ruining the CCS metric. The generated blueprint solves this by mandating strict regex for FEVER and introducing a fallback LLM-as-a-judge (Token-F1 + GPT-4o-mini) for the HotpotQA multi-hop task.
* **Scope Gating:** The behavioral distillation (Discriminator) was identified in the inputs as a risk for scope creep. The work division strictly isolates this to Mohamad and mandates a "Trigger Decision" in Week 3—it only proceeds if the core CCS pipeline is flawless.

4. Validation against Reference Material

* **Tone:** The output maintains the authoritative, prescriptive, engineering-first tone of the reference autonomous driving package.
* **Depth:** It moves beyond the theoretical "we will chunk the text" to specify *how* (using `spaCy` to avoid mid-sentence cuts) and *how to serve it* (using `vLLM` for batched throughput to handle $O(K \times N)$ expansions).
* **Alignment:** All team member names, project goals, datasets (FEVER, HotpotQA), and models (GPT2-XL, Qwen2.5) align perfectly with the constraints provided in the raw target inputs. No external assumptions overrode the explicit boundaries of the MemFaith prompt. All cross-file consistency requirements (Title, Team, Task definitions, Timeline) are rigorously maintained across the five deliverables.
